

PHOTO-IDENTIFICATION OF THE VAQUITA (*PHOCOENA SINUS*): THE WORLD'S MOST ENDANGERED CETACEAN¹

THOMAS A. JEFFERSON^{2*}, PAULA A. OLSON², THOMAS R. KIECKHEFER³ AND LORENZO ROJAS-BRACHO⁴

The vaquita (*Phocoena sinus*) has been recognized as a rare and vulnerable species since its scientific discovery just over fifty years ago (Norris and McFarland, 1958). There are a number of potential threats facing the species, and its limited range in shallow waters of the upper portion of Mexico's Gulf of California is the smallest of any marine cetacean.

Without a doubt the primary threat is incidental kills of porpoises in various fisheries, mainly several gillnet fisheries (Rojas-Bracho and Taylor, 1999; Rojas-Bracho *et al.*, 2006). The vaquita is listed as Critically Endangered on the IUCN Red List. With the recent discovery that the baiji (*Lipotes vexillifer*) is most likely extinct (Turvey *et al.*, 2007), the vaquita is now recognized as the most endangered cetacean species in the world. There were estimated to be only about 150 vaquitas remaining in 2007 (Jaramillo-Legorreta *et al.*, 2007).

In the autumn of 2008, a large-scale international effort to study the vaquita and develop methods to monitor its population status was conducted. As part of this effort, we investigated the feasibility of getting high-quality photos of vaquitas and of using photo-identification methods. From 2-30 October 2008, we conducted small-vessel surveys for vaquitas from a shore-based station in San Felipe, Baja California Norte, Mexico. Each day, weather permitting, we traveled offshore to the region where past vaquita sightings had been concentrated (between San Felipe and Rocas Consag, a small island about 30 km offshore- Jaramillo-Legorreta *et al.*, 2007.). We searched for vaquitas while the vessel was moving, but also periodically conducted 'stop and drift' searches, in which the vessel's engine and depth sounder were shut down, and 3-6 observers searched the area with naked eye and binoculars.

Two vessels were used: from 2-10 October, we used the *Ema Luz*, a 6.4-m outboard motor boat, which is similar to the vessels gillnet fishermen use in the area to tend their nets (locally called *pangas*). From 11-30 October, we used the *Pancho Villa*, a 17-m sportfishing vessel based in Puerto Peñasco. The *Pancho Villa* was much more stable and seaworthy, with a higher platform and much greater suitability for observations.

When vaquitas were observed, basic sighting data were collected (e.g., date, time, position, sighting conditions, group size, behavior), and we attempted to obtain

photos. This could involve remaining with the boat engine turned off or in neutral (if the animals were within 150m or so), or moving closer to the group at slow speed with the engine in gear. Photos were taken with Canon EOS 20D, 30D, and 40D digital cameras (8.2 or 10.1 megapixels) and a variety of L-series zoom and telephoto lenses, ranging up to 400mm in focal length. A 1.4X or 2X converter was used with some of the lenses.

We conducted surveys on 20 days; poor weather (winds causing sea states of Beaufort 4 or above) prevented us from surveying on the remaining nine days. We searched 1,229km while moving, and conducted 51 'stop and drift' searches making up a total of 50 hours. We sighted 13 groups of vaquitas (all between 18 and 30 October).

Vaquita sightings occurred both during 'stop and drift' searches (n=7) and during searches while traveling (n=6). Most sightings occurred in calm sea states of Beaufort 0-2 (winds < 12km/h), with only one in a Beaufort 3 – the average sea state during vaquita sightings was $0.9 \pm s.d. 0.83$ (n=13). This emphasizes the importance of calm seas for sighting vaquitas. Group size ranged from 1-9 individuals, with a mean of $3.2 \pm s.d. 2.19$. The largest groups generally appeared to be loose aggregations of several smaller subgroups of 1-4 individuals.

Calves were observed in at least four of the sightings, although these all appeared to be larger 'juveniles', rather than neonates. This is in agreement with the known spring calving season of the species (Hohn *et al.*, 1996). Juveniles were slightly darker in color than the adults that accompanied them (as shown in Fig.1 of Brownell *et al.*, 1987). Most of the groups observed appeared to be either milling/feeding or traveling. Responses to the vessel ranged from avoidance to no response, and in one case apparent attraction, as two individuals swam directly toward our idling vessel and passed almost directly beneath the bow.

Photos of vaquitas were taken during eight of the sightings; 1,653 frames were taken. On four different days vaquita images were obtained that were adequate for photo-identification. This is the first time that vaquitas have been photo-identified, although Silber *et al.* (1988, p. 64) did previously report a sighting of a female with 'two prominent nicks in the trailing edge' of the dorsal fin. We identified six individuals based on their natural markings (dorsal fin nicks, fin and body scars – Figure 1).

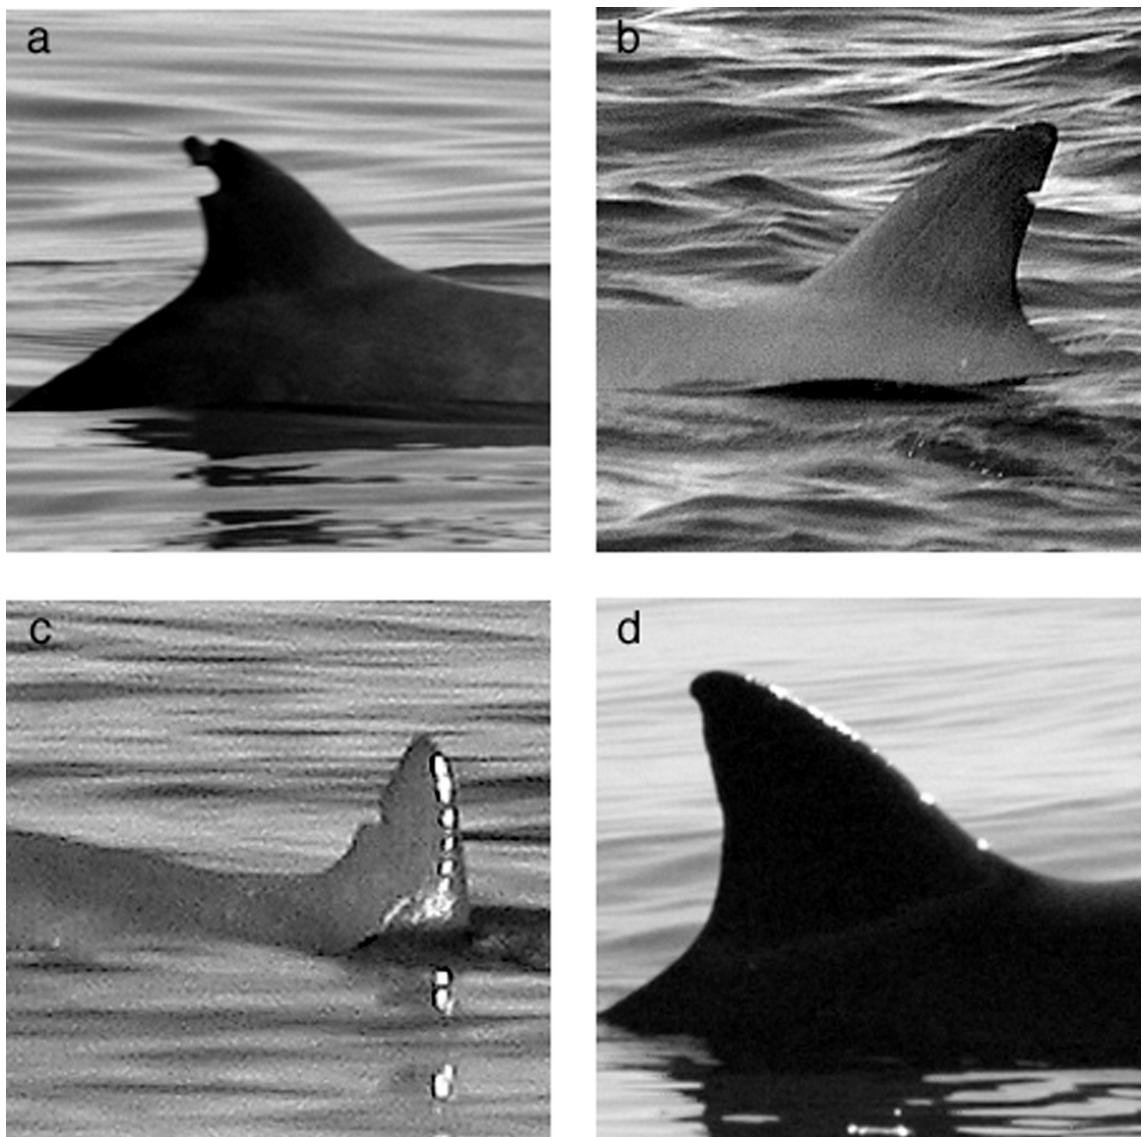

Figure 1. Four individual vaquitas that were photo-identified by dorsal fin shape and nicks: a. Nicola (a presumed female with two large notches), b. Topnick (an individual with a single triangular nick 2/3 of the way up the dorsal fin), c. Midnick (an individual with a single triangular nick 1/2 of the way up the dorsal fin), and d. Fingertip (a presumed female with an unusually-shaped dorsal fin).

However, two of these possessed only body scars that would likely not last long enough for multi-year identification (Figure 2). We also observed and photographed a number of scars on the heads of some individuals, although these were deemed inadequate for photo-ID, based on how infrequently vaquitas show their heads. All photographed individuals appeared healthy, with no evidence of malnutrition or dermal disease.

Many porpoises did not appear to possess usable distinctive features on their backs or dorsal fins, even in high-quality, sharp images. We obtained good-quality photos of two juvenile individuals, but neither of these was individually identifiable. Of the 13-17 different adults that we estimate we photographed well

over the study, six individuals could be identified reliably, at least within one field season. If this small sample is representative of the population, it suggests that between 35% and 46% of adults possess markings that would allow them to be identified within a season. Based on this sample, and considering only those with long-term markings, an estimated 24-31% of adults would be suitable for long-term photo-identification. This is higher than the 17-21% estimated for Dall's porpoise (*Phocoenoides dalli* - Miller, 1990), and might be related to the relatively larger dorsal fins of vaquitas and the more shallow nature of their habitat (i.e., contact with the sea floor would presumably increase scarring opportunities). Although attempts have been made to identify individual harbor (*Phocoena phocoena* - Watson, 1976;

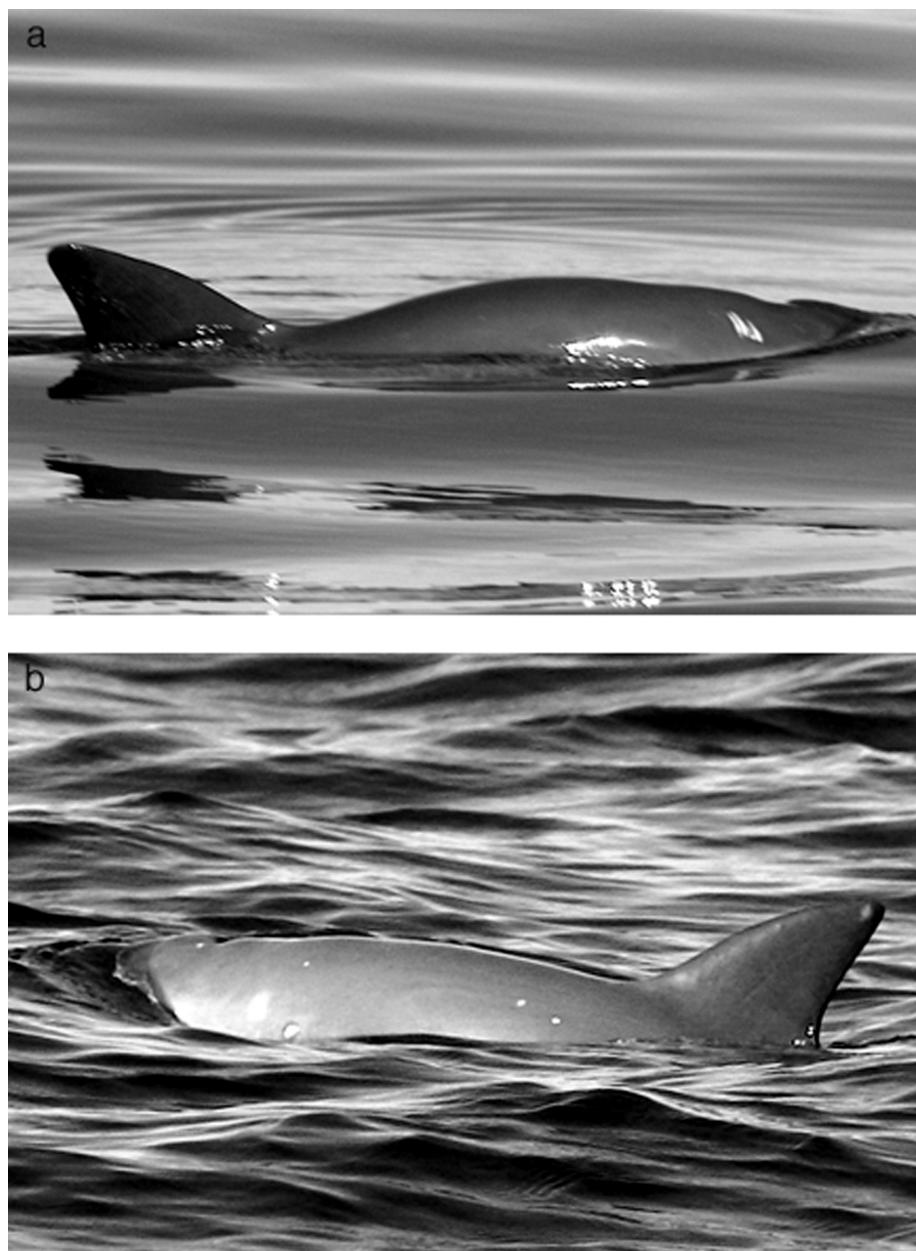

Figure 2. Two vaquita individuals that were identified by body scarring. Neither of these animals is considered to be identifiable in the long term.

Watson and Gaskin, 1983) and finless (*Neophocaena phocaenoides* - Jefferson, unpubl. data) porpoises by natural markings, photo-identification techniques have never been successfully applied to other species of the genus *Phocoena*. This study has demonstrated that, despite their rarity and cryptic nature, vaquitas can be photo-identified. We are optimistic that future efforts can obtain even better photos, and that individual vaquitas can be tracked over time. Even limited success at photo-identification of this critically-endangered species may provide valuable information. In fact, with any

kind of tagging work being infeasible for such a rare species, photo-identification may be the only way to get at many critical pieces of information. Any future photo-identification work will be facilitated by new technological advances (such as digital SLR cameras with high-resolution video), and should attempt to use a relatively large (>15m), stable vessel that allows for eye heights of at least several meters above the surface; *pangas* are not good vessels for this kind of work. In order to learn more about the vaquita, we plan to pursue further photo-identification studies.

Acknowledgements

Many people and organizations were involved in the successful completion of this project. It would not have been possible without the collaboration of our colleagues from NOAA, especially B. Taylor, L. Ballance, R. Pitman, S. Mesnick, A. Henry, S. Rankin, N. Kellar, and G. Serra-Valente. C. Johnson was great field partner and we thoroughly enjoyed our times together at sea and on land. A. Jaramillo was also helpful, and we were fortunate to have the assistance of G. Silber on one day. We would like to thank our expert boat drivers and crew: A. Herrera, R. Ramirez, A. Vasquez, Ricardo and Pablo. H. Chan and L. Jefferson assisted us in the field. This project was funded by the Whale and Dolphin Conservation Society (UK), World Wildlife Fund (US), Natural Resources Defense Council (US), and a US foundation that prefers to remain anonymous. Cetos Research Organization provided financial support, and we particularly thank A. Zoidis. The photos were taken under permit (Oficio No. DR/488/08 from the Comisión Nacional de Áreas Naturales Protegidas (CONANP/Secretaría del Medio Ambiente y Recursos Naturales (SEMARNAT), within a natural protected area subject to special management and decreed as such by the Mexican Government. J. Campoy was instrumental in helping to obtain our permit. Comments from B. Taylor, J. Urbán, W. Perrin, and S. Mesnick improved the manuscript.
